GENERAL DESCRIPTION

The ADG528F[1] is a CMOS analog multiplexer, with the comprising eight single channels. This multiplexer provides fault protection. Using a series n-channel, p-channel, n-channel MOSFET structure, both device and signal source protection is provided in the event of an overvoltage or power loss. The multiplexer can withstand continuous overvoltage inputs from −40 V to +55 V. During fault conditions, the multiplexer input (or output) appears as an open circuit and only a few nanoamperes of leakage current will flow. This protects not only the multiplexer and the circuitry driven by the multiplexer, but also protects the sensors or signal sources that drive the multiplexer.

The ADG528F switches one of eight inputs to a common output as determined by the 3-bit binary address lines A0, A1, and A2. The ADG528F has on-chip address and control latches that facilitate microprocessor interfacing. An EN input on the device is used to enable or disable the device. When disabled, all channels are switched off.

PRODUCT HIGHLIGHTS

1. Fault protection.
   The ADG528F can withstand continuous voltage inputs from −40 V to +55 V. When a fault occurs due to the power supplies being turned off, all the channels are turned off and only a leakage current of a few nanoamperes flows.
2. On channel turns off while fault exists.
3. Low R_{ON}.
4. Fast switching times.
5. Break-before-make switching.
   Switches are guaranteed break-before-make so that input signals are protected against momentary shorting.
6. Trench isolation eliminates latch-up.
   A dielectric trench separates the p-channel and n-channel MOSFETs thereby preventing latch-up.

TIMING DIAGRAMS

Figure 2 shows the timing sequence for latching the switch address and enable inputs. The latches are level sensitive; therefore, while $\overline{WR}$ is held low, the latches are transparent and the switches respond to the address and enable inputs.

This input data is latched on the rising edge of $\overline{WR}$. Figure 3 shows the reset pulse width, t_{RS}, and the reset turnoff time, t_{OFF} ($\overline{RS}$). Note that all digital input signals rise and fall times are measured from 10% to 90% of 3 V. $t_R = t_F = 20$ ns.

THEORY OF OPERATION

The ADG528F multiplexer is capable of withstanding overvoltages from −40 V to +55 V, irrespective of whether the power supplies are present or not. Each channel of the multiplexer consists of an n-channel MOSFET, a p-channel MOSFET, and an n-channel MOSFET, connected in series. When the analog input exceeds the power supplies, one of the MOSFETs will switch off, limiting the current to submicroamp levels, thereby preventing the overvoltage from damaging any circuitry following the multiplexer. Figure 14 illustrates the channel architecture that enables these multiplexers to withstand continuous overvoltages.

When an analog input of V_{SS} + 3 V to V_{DD} − 1.5 V is applied to the ADG528F, the multiplexer behaves as a standard multiplexer, with specifications similar to a standard multiplexer, for example, the on-resistance is 400 Ω maximum. However, when an overvoltage is applied to the device, one of the three MOSFETs will turn off.

Figure 14 to Figure 17 show the conditions of the three MOSFETs for the various overvoltage situations. When the analog input applied to an on channel approaches the positive power supply line, the n-channel MOSFET turns off because the voltage on the analog input exceeds the difference between V_{DD} and the n-channel threshold voltage (V_{TN}). When a voltage more negative than V_{SS} is applied to the multiplexer, the p-channel MOSFET will turn off because the analog input is more negative than the difference between V_{SS} and the p-channel threshold voltage (V_{TP}). Because V_{TN} is nominally 1.5 V and V_{TP} is typically 3 V, the analog input range to the multiplexer is limited to −12 V to +13.5 V when a ±15 V power supply is used.

When the power supplies are present but the channel is off, again either the p-channel MOSFET or one of the n-channel MOSFETs will turn off when an overvoltage occurs.

Finally, when the power supplies are off, the gate of each MOSFET will be at ground. A negative overvoltage switches on the first n-channel MOSFET but the bias produced by the overvoltage causes the p-channel MOSFET to remain turned off. With a positive overvoltage, the first MOSFET in the series will remain off because the gate to source voltage applied to this MOSFET is negative.

During fault conditions, the leakage current into and out of the ADG528F is limited to a few microamps. This protects the multiplexer and succeeding circuitry from over stresses as well as protecting the signal sources, which drive the multiplexer. Also, the other channels of the multiplexer will be undisturbed by the overvoltage and will continue to operate normally.
