## FEATURES

Excellent Sonic Characteristics
Low Noise: $6 \mathrm{nV} / \sqrt{\mathrm{Hz}}$
Low Distortion: 0.0006\%
High Slew Rate: 22 V/ $\mu \mathrm{s}$
Wide Bandwidth: 9 MHz
Low Supply Current: 5 mA
Low Offset Voltage: 1 mV
Low Offset Current: 2 nA
Unity Gain Stable
SOIC-8 Package
PDIP-8 Package

## APPLICATIONS

High Performance Audio
Active Filters
Fast Amplifiers
Integrators

## GENERAL DESCRIPTION

The OP275 is the first amplifier to feature the Butler Amplifier front end. This new front end design combines both bipolar and JFET transistors to attain amplifiers with the accuracy and low noise performance of bipolar transistors, and the speed and sound quality of JFETs. Total Harmonic Distortion plus Noise equals that of previous audio amplifiers, but at much lower supply currents.

A very low l/f corner of below 6 Hz maintains a flat noise density response. Whether noise is measured at either 30 Hz or 1 kHz , it is only $6 \mathrm{nV} \sqrt{\mathrm{Hz}}$. The JFET portion of the input stage gives the OP275 its high slew rates to keep distortion low, even when large output swings are required, and the $22 \mathrm{~V} / \mu \mathrm{s}$ slew rate of the OP275 is the fastest of any standard audio amplifier. Best of all, this low noise and high speed are accomplished using less than 5 mA of supply current, lower than any standard audio amplifier.

## NOTES

${ }^{1}$ Absolute maximum ratings apply to packaged parts, unless otherwise noted.
${ }^{2}$ For supply voltages greater than $\pm 22 \mathrm{~V}$, the absolute maximum input voltage is equal to the supply voltage.
${ }^{3}$ Shorts to either supply may destroy the device. See data sheet for full details.
${ }^{4} \theta_{\mathrm{JA}}$ is specified for the worst-case conditions, i.e., $\theta_{\mathrm{JA}}$ is specified for device in socket for PDIP packages; $\theta_{\mathrm{JA}}$ is specified for device soldered in circuit board for SOIC packages.

*Z = Pb-free part.

## CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the OP275 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

## APPLICATIONS

## Circuit Protection

OP275 has been designed with inherent short-circuit protection to ground. An internal $30 \Omega$ resistor, in series with the output, limits the output current at room temperature to $\mathrm{I}_{\mathrm{SC}}+=40 \mathrm{~mA}$ and $\mathrm{I}_{\mathrm{SC}^{-}}=-90 \mathrm{~mA}$, typically, with $\pm 15 \mathrm{~V}$ supplies.
However, shorts to either supply may destroy the device when excessive voltages or currents are applied. If it is possible for a user to short an output to a supply for safe operation, the output current of the OP275 should be design-limited to $\pm 30 \mathrm{~mA}$, as shown in Figure 1.

## Total Harmonic Distortion

Total Harmonic Distortion + Noise (THD + N) of the OP275 is well below $0.001 \%$ with any load down to $600 \Omega$. However, this is dependent upon the peak output swing. In Figure 2, the THD + Noise with 3 V rms output is below $0.001 \%$. In Figure 3, THD + Noise is below $0.001 \%$ for the $10 \mathrm{k} \Omega$ and $2 \mathrm{k} \Omega$ loads but increases to above $0.1 \%$ for the $600 \Omega$ load condition. This is a result of the output swing capability of the OP275. Notice the results in Figure 4, showing THD versus $\mathrm{V}_{\text {IN }}(\mathrm{V} \mathrm{rms})$. This figure shows that the THD + Noise remains very low until the output reaches 9.5 V rms . This performance is similar to competitive products.

Figure 1. Recommended Output Short-Circuit Protection

Figure 2. THD + Noise vs. Frequency vs. $R_{\text {LOAD }}$

Figure 3. $T H D+$ Noise vs. $R_{\text {LOAD }} ; V_{I N}=10 \mathrm{~V} \mathrm{rms}$

Figure 4. Headroom, THD + Noise vs. Output Amplitude ( V rms ); $R_{\text {LOAD }}=600 \Omega, V_{\text {SUP }}= \pm 18 \mathrm{~V}$

The output of the OP275 is designed to maintain low harmonic distortion while driving $600 \Omega$ loads. However, driving $600 \Omega$ loads with very high output swings results in higher distortion if clipping occurs. A common example of this is in attempting to drive 10 V rms into any load with $\pm 15 \mathrm{~V}$ supplies. Clipping will occur and distortion will be very high. To attain low harmonic distortion with large output swings, supply voltages may be increased. Figure 5 shows the performance of the OP275 driving $600 \Omega$ loads with supply voltages varying from $\pm 18 \mathrm{~V}$ to $\pm 20 \mathrm{~V}$. Notice that with $\pm 18 \mathrm{~V}$ supplies the distortion is fairly high, while with $\pm 20 \mathrm{~V}$ supplies it is a very low $0.0007 \%$.

Figure 5. THD + Noise vs. Supply Voltage

## Noise

The voltage noise density of the OP275 is below $7 \mathrm{nV} / \sqrt{\mathrm{Hz}}$ from 30 Hz . This enables low noise designs to have good performance throughout the full audio range. Figure 6 shows a typical OP275 with a $1 / \mathrm{f}$ corner at 2.24 Hz .

Figure 6. $1 /$ f Noise Corner, $V_{S}= \pm 15 \mathrm{~V}, A_{V}=1000$

## Noise Testing

For audio applications, the noise density is usually the most important noise parameter. For characterization, the OP275 is tested using an Audio Precision, System One. The input signal to the Audio Precision must be amplified enough to measure it accurately. For the OP275, the noise is gained by approximately 1020 using the circuit shown in Figure 7. Any readings on the Audio Precision must then be divided by the gain. In implementing this test fixture, good supply bypassing is essential.

Figure 7. Noise Test Fixture

## Input Overcurrent Protection

The maximum input differential voltage that can be applied to the OP275 is determined by a pair of internal Zener diodes connected across its inputs. They limit the maximum differential input voltage to $\pm 7.5 \mathrm{~V}$. This is to prevent emitter-base junction breakdown from occurring in the input stage of the OP275 when very large differential voltages are applied. However, to preserve the OP275's low input noise voltage, internal resistances in series with the inputs were not used to limit the current in the clamp diodes. In small signal applications, this is not an issue; however, in applications where large differential voltages can be inadvertently applied to the device, large transient currents can flow through these diodes. Although these diodes have been designed to carry a current of $\pm 5 \mathrm{~mA}$, external resistors as shown in Figure 8 should be used in the event that the OP275's differential voltage were to exceed $\pm 7.5 \mathrm{~V}$.

Figure 8. Input Overcurrent Protection

## Output Voltage Phase Reversal

Since the OP275's input stage combines bipolar transistors for low noise and p-channel JFETs for high speed performance, the output voltage of the OP275 may exhibit phase reversal if either of its inputs exceeds its negative common-mode input voltage. This might occur in very severe industrial applications where a sensor or system fault might apply very large voltages on the inputs of the OP275. Even though the input voltage range of the OP275 is $\pm 10.5 \mathrm{~V}$, an input voltage of approximately -13.5 V will cause output voltage phase reversal. In inverting amplifier configurations, the OP275's internal 7.5 V input clamping diodes will
prevent phase reversal; however, they will not prevent this effect from occurring in noninverting applications. For these applications, the fix is a simple one and is illustrated in Figure 9. A $3.92 \mathrm{k} \Omega$ resistor in series with the noninverting input of the OP275 cures the problem.

Figure 9. Output Voltage Phase Reversal Fix

## Overload or Overdrive Recovery

Overload or overdrive recovery time of an operational amplifier is the time required for the output voltage to recover to a rated output voltage from a saturated condition. This recovery time is important in applications where the amplifier must recover quickly after a large abnormal transient event. The circuit shown in Figure 10 was used to evaluate the OP275's overload recovery time. The OP275 takes approximately 1.2 ms to recover to $\mathrm{V}_{\text {OUT }}=$ +10 V and approximately $1.5 \mu$ s to recover to $\mathrm{V}_{\mathrm{OUT}}=-10 \mathrm{~V}$.

Figure 10. Overload RecoveryTime Test Circuit

## Measuring Settling Time

The design of OP275 combines a high slew rate and a wide gain bandwidth product to produce a fast settling ( $\mathrm{t}_{\mathrm{S}}<1 \mu \mathrm{~s}$ ) amplifier for 8 - and 12-bit applications. The test circuit designed to measure the settling time of the OP275 is shown in Figure 11. This test method has advantages over false-sum node techniques in that the actual output of the amplifier is measured, instead of an error voltage at the sum node. Common-mode settling effects are exercised in this circuit in addition to the slew rate and bandwidth effects measured by the false-sum node method. Of course, a reasonably flat-top pulse is required as the stimulus.

The output waveform of the OP275 under test is clamped by Schottky diodes and buffered by the JFET source follower. The signal is amplified by a factor of 10 by the OP260 and then Schottky-clamped at the output to prevent overloading the oscilloscope's input amplifier. The OP41 is configured as a fast integrator, which provides overall dc offset nulling.

## High Speed Operation

As with most high speed amplifiers, care should be taken with supply decoupling, lead dress, and component placement. Recommended circuit configurations for inverting and noninverting applications are shown in Figures 12 and 13.

Figure 11. OP275's Settling Time Test Fixture

Figure 12. Unity Gain Follower

Figure 13. Unity Gain Inverter
In inverting and noninverting applications, the feedback resistance forms a pole with the source resistance and capacitance ( $\mathrm{R}_{\mathrm{S}}$ and $\mathrm{C}_{\mathrm{S}}$ ) and the OP275's input capacitance ( $\mathrm{C}_{\mathrm{IN}}$ ), as shown in Figure 14. With $R_{S}$ and $R_{F}$ in the kilohm range, this pole can create excess phase shift and even oscillation. A small capacitor, $\mathrm{C}_{\mathrm{FB}}$, in parallel and $\mathrm{R}_{\mathrm{FB}}$ eliminates this problem. By setting $R_{S}\left(C_{S}+C_{I N}\right)=R_{F B} C_{F B}$, the effect of the feedback pole is completely removed.

Figure 14. Compensating the Feedback Pole

## Attention to Source Impedances Minimizes Distortion

Since the OP275 is a very low distortion amplifier, careful attention should be given to source impedances seen by both inputs. As with many FET-type amplifiers, the p-channel JFETs in the OP275's input stage exhibit a gate-to-source capacitance that varies with the applied input voltage. In an inverting configuration, the inverting input is held at a virtual ground and, as such, does not vary with input voltage. Thus, since the gate-to-source voltage is constant, there is no distortion due to input capacitance modulation. In noninverting applications, however, the gate-to-source voltage is not constant. The resulting capacitance modulation can cause distortion above 1 kHz if the input impedance is greater than $2 \mathrm{k} \Omega$ and unbalanced.

Figure 15. Balanced Input Impedance to Minimize Distortion in Noninverting Amplifier Circuits
Figure 15 shows some guidelines for maximizing the distortion performance of the OP275 in noninverting applications. The best way to prevent unwanted distortion is to ensure that the parallel combination of the feedback and gain setting resistors ( $\mathrm{R}_{\mathrm{F}}$ and $\mathrm{R}_{\mathrm{G}}$ ) is less than $2 \mathrm{k} \Omega$. Keeping the values of these resistors small has the added benefits of reducing the thermal noise of the circuit
and dc offset errors. If the parallel combination of $R_{F}$ and $R_{G}$ is larger than $2 \mathrm{k} \Omega$, then an additional resistor, $\mathrm{R}_{\mathrm{S}}$, should be used in series with the noninverting input. The value of $R_{S}$ is determined by the parallel combination of $\mathrm{R}_{\mathrm{F}}$ and $\mathrm{R}_{\mathrm{G}}$ to maintain the low distortion performance of the OP275.

## Driving Capacitive Loads

The OP275 was designed to drive both resistive loads to $600 \Omega$ and capacitive loads of over 1000 pF and maintain stability. While there is a degradation in bandwidth when driving capacitive loads, the designer need not worry about device stability. The graph in Figure 16 shows the 0 dB bandwidth of the OP275 with capacitive loads from 10 pF to 1000 pF .

Figure 16. Bandwidth vs. $C_{\text {LOAD }}$
High Speed, Low Noise Differential Line Driver The circuit in Figure 17 is a unique line driver widely used in industrial applications. With $\pm 18 \mathrm{~V}$ supplies, the line driver can deliver a differential signal of 30 V p-p into a $2.5 \mathrm{k} \Omega$ load. The high slew rate and wide bandwidth of the OP275 combine to yield a full power bandwidth of 130 kHz while the low noise front end produces a referred-to-input noise voltage spectral density of $10 \mathrm{nV} / \sqrt{\mathrm{Hz}}$.

Figure 17. High Speed, Low Noise Differential Line Driver

The design is a transformerless, balanced transmission system where output common-mode rejection of noise is of paramount importance. Like the transformer based design, either output can be shorted to ground for unbalanced line driver applications without changing the circuit gain of 1 . Other circuit gains can be set according to the equation in the diagram. This allows the design to be easily set to noninverting, inverting, or differential operation.

## A 3-Pole, 40 kHz Low-Pass Filter

The closely matched and uniform ac characteristics of the OP275 make it ideal for use in GIC (Generalized Impedance Converter) and FDNR (Frequency-Dependent Negative Resistor) filter applications. The circuit in Figure 18 illustrates a linear-phase, 3-pole, 40 kHz low-pass filter using an OP275 as an inductance simulator (gyrator). The circuit uses one OP275 (A2 and A3) for the FDNR and one OP275 (A1 and A4) as an input buffer and bias current source for A3. Amplifier A4 is configured in a gain of 2 to set the pass band magnitude response to 0 dB . The benefits of this filter topology over classical approaches are that the op amp used in the FDNR is not in the signal path and that the filter's performance is relatively insensitive to component variations. Also, the configuration is such that large signal levels can be handled without overloading any of the filter's internal nodes. As shown in Figure 19, the OP275's symmetric slew rate and low distortion produce a clean, well behaved transient response.
