# +3V, 400ksps, 4/8-Channel, 8-Bit ADCs with 1 $\mu$ A Power-Down 

## General Description

The MAX113/MAX117 are microprocessor-compatible, 8-bit, 4-channel and 8-channel analog-to-digital converters (ADCs). They operate from a single +3 V supply and use a half-flash technique to achieve a $1.8 \mu$ s conversion time (400ksps). A power-down pin (PWRDN) reduces current consumption to $1 \mu \mathrm{~A}$ typical. The devices return from power-down mode to normal operating mode in less than 900 ns , allowing large supplycurrent reductions in burst-mode applications. (In burst mode, the ADC wakes up from a low-power state at specified intervals to sample the analog input signals.) Both converters include a track/hold, enabling the ADC to digitize fast analog signals.
Microprocessor ( $\mu \mathrm{P}$ ) interfaces are simplified because the ADC can appear as a memory location or I/O port without external interface logic. The data outputs use latched, three-state buffer circuitry for direct connection to an 8-bit parallel $\mu \mathrm{P}$ data bus or system input port. The MAX113/MAX117 input/reference configuration enables ratiometric operation.
The 4-channel MAX113 is available in a 24-pin DIP or SSOP. The 8-channel MAX117 is available in a 28 -pin DIP or SSOP. For +5 V applications, refer to the MAX114/MAX118 data sheet.

Applications

Battery-Powered Systems
System-Health Monitoring
Communications Systems

Portable Equipment
Remote Data Acquisition

- +3.0V to +3.6V Single-Supply Operation
- 4 (MAX113) or 8 (MAX117) Analog Input Channels
- Low Power: 1.5mA (operating mode)
- Total Unadjusted Error $\leq 1$ LSB
- Fast Conversion Time: 1.8 $\mu$ s per Channel
- No External Clock Required
- Internal Track/Hold
- Ratiometric Reference Inputs
- Internally Connected 8th Channel Monitors Reference Voltage (MAX117)

| PART | TEMP. RANGE | PIN-PACKAGE |
| :--- | :---: | :--- |
| MAX113CNG | $0^{\circ} \mathrm{C}$ to $+70^{\circ} \mathrm{C}$ | 24 Narrow Plastic DIP |

Figure 1. Load Circuits for Data-Access Time Test

## Detailed Description

## Converter Operation

The MAX113/MAX117 use a half-flash conversion technique (see Functional Diagram) in which two 4-bit flash ADC sections achieve an 8-bit result. Using 15 comparators, the flash ADC compares the unknown input voltage to the reference ladder and provides the upper four data bits. An internal digital-to-analog converter (DAC) uses the four most significant bits (MSBs) to generate both the analog result from the first flash conversion and a residue voltage that is the difference between the unknown input and the DAC voltage. The residue is then compared again with the flash comparators to obtain the lower four data bits (LSBs).
An internal analog multiplexer enables the devices to read four (MAX113) or eight (MAX117) different analog voltages under microprocessor ( $\mu \mathrm{P}$ ) control. One of the MAX117's analog channels, IN8, is internally hardwired and always reads $\mathrm{V}_{\text {REF }}$ when selected.

## Power-Down Mode

In burst-mode or low-sample-rate applications, the MAX113/MAX117 can be shut down between conversions, reducing supply current to microamp levels (see Typical Operating Characteristics). A logic low on the $\overline{\text { PWRDN }}$ pin shuts the devices down, reducing supply current typically to $1 \mu \mathrm{~A}$ when powered from a single +3 V supply. A logic high on PWRDN wakes up the MAX113/MAX117, and the selected analog input enters the track mode. The signal is fully acquired after 900ns (this includes both the power-up delay and the track/hold acquisition time), and a new conversion can

Figure 2. Load Circuits for Data-Hold Time Test
be started. If the power-down feature is not required, connect $\overline{\text { PWRDN }}$ to VDD. For minimum current consumption, keep digital inputs at the supply rails in power-down mode. Refer to the Reference section for information on reducing the reference current during power-down.

## Digital Interface

The MAX113/MAX117 have two basic interface modes, which are set by the MODE pin. When MODE is low, the converters are in read mode; when MODE is high, the converters are set up for write-read mode. The A0, A1, and A2 inputs control channel selection, as shown in Table 1. The address must be valid for a minimum time, $\mathrm{t}_{\mathrm{ACQ}}$, before the next conversion starts.

# +3V, 400ksps, 4/8-Channel, 8-Bit ADCs with 1 1 A Power-Down 

## Read Mode (MODE $=0$ )

In read mode, conversions and data access are controlled by the $\overline{R D}$ input (Figure 3). The comparator inputs track the analog input voltage for the duration of tACQ. A conversion is initiated by driving $\overline{\mathrm{CS}}$ and $\overline{\mathrm{RD}}$ low. With $\mu$ Ps that can be forced into a wait state, hold $\overline{R D}$ low until output data appears. The $\mu \mathrm{P}$ starts the conversion, waits, and then reads data with a single read instruction.
In read mode, $\overline{W R} / R D Y$ is configured as a status output (RDY), so it can drive the ready or wait input of a $\mu \mathrm{P}$. RDY is an open-collector output (no internal pull-up) that goes low after the falling edge of $\overline{\mathrm{CS}}$ and goes high at the end of the conversion. If not used, the WR/RDY pin can be left unconnected. The INT output goes low at the end of the conversion and returns high on the rising edge of $\overline{\mathrm{CS}}$ or $\overline{\mathrm{RD}}$.

## Write-Read Mode (MODE = 1)

Figures 4 and 5 show the operating sequence for writeread mode. The comparator inputs track the analog input voltage for the duration of $t_{A C Q}$. The conversion is initiated by a falling edge of WR. When WR returns high, the result of the four-MSBs flash is latched into the output buffers and the conversion of the four-LSBs flash starts. INT goes low, indicating conversion end, and the lower four data bits are latched into the output buffers. The data is then accessible after $\overline{R D}$ goes low (see Timing Characteristics).
A minimum acquisition time ( tACQ ) is required from $\overline{\mathrm{INT}}$ going low to the start of another conversion ( $\overline{\mathrm{WR}}$ going low).
Options for reading data from the converter include using internal delay, reading before delay, and pipelined operation (discussed in the following sections).

Using Internal Delay
The $\mu \mathrm{P}$ waits for the $\overline{\mathrm{INT}}$ output to go low before reading the data (Figure 4). INT goes low after the rising edge of $\overline{W R}$, indicating that the conversion is complete and the result is available in the output latch. With $\overline{\mathrm{CS}}$ low, data outputs D0-D7 can be accessed by pulling $\overline{R D}$ low. INT is then reset by the rising edge of $\overline{C S}$ or $\overline{\mathrm{RD}}$.

## Fastest Conversion: <br> Reading Before Delay

An external method of controlling the conversion time is shown in Figure 5. The internally generated delay (tINTL) varies slightly with temperature and supply voltage, and can be overridden with $\overline{\mathrm{RD}}$ to achieve the fastest conversion time. $\overline{\mathrm{RD}}$ is brought low after the rising edge of $\overline{W R}$, but before $\overline{\text { INT }}$ goes low. This completes the conversion and enables the output buffers

Figure 6. Pipelined Mode Timing $(\overline{W R}=\overline{R D})($ Mode $=1)$
that contain the conversion result (D0-D7). $\overline{\mathrm{NT}}$ also goes low after the falling edge of RD and is reset on the rising edge of $\overline{\mathrm{RD}}$ or CS . The total conversion time is therefore: $\mathrm{twR}+\mathrm{tRD}+\mathrm{taCC} 1=1800 \mathrm{~ns}$.

## Pipelined Operation

Besides the two standard write-read-mode options, "pipelined" operation can be achieved by connecting $\overline{W R}$ and $\overline{R D}$ together (Figure 6). With $\overline{C S}$ low, driving $\overline{W R}$ and $\overline{\mathrm{RD}}$ low initiates a conversion and concurrently reads the result of the previous conversion.

## Analog Considerations

Reference
Figures 7a, 7b, and 7c show typical reference connections. The voltages at REF+ and REF- set the ADC's analog input range (Figure 10). The voltage at REFdefines the input that produces an output code of all zeros, and the voltage at REF+ defines the input that produces an output code of all ones.
The internal resistance from REF+ to REF- can be as low as $1 \mathrm{k} \Omega$, and current will flow through it even when the MAX113/MAX117 are shut down. Figure 7d shows how an N-channel MOSFET can be connected to REFto break this current path during power-down. The FET should have an on-resistance of less than $2 \Omega$ with a 3 V gate drive. When REF- is switched, as in Figure 7d, a new conversion can be initiated after waiting a time equal to the power-up delay (tUP) plus the N-channel FET's turn-on time.
Although REF+ is frequently connected to $\mathrm{V}_{\mathrm{DD}}$, the circuit of Figure 7d uses a low-current, low-dropout, 2.5 V voltage reference: the MAX872. Since the MAX872 cannot continuously furnish enough current for the ref-

Figure 7b. External Reference, 2.5V Full Scale

Figure 7c. Input Not Referenced to GND
erence resistance, this circuit is intended for applications where the MAX113/MAX117 are normally in standby and are turned on in order to make measurements at intervals greater than $100 \mu \mathrm{~s}$. C1 (the capacitor connected to REF+) is slowly charged by the MAX872 during the standby period, and furnishes the reference current during the short measurement period.
The $4.7 \mu \mathrm{~F}$ value of C 1 ensures a voltage drop of less than $1 / 2$ LSB when performing four to eight successive conversions. Larger capacitors reduce the error still further. Use ceramic or tantalum capacitors for C1.

## +3V, 400ksps, 4/8-Channel, 8-Bit ADCs with 1 1 A Power-Down

Figure 7d. An N-channel MOSFET switches off the reference load during power-down

## Initial Power-Up

When power is first applied, perform a conversion to initialize the MAX113/MAX117. Disregard the output data.

Bypassing
Use a $4.7 \mu \mathrm{~F}$ electrolytic in parallel with a $0.1 \mu \mathrm{~F}$ ceramic capacitor to bypass VDD to GND. Minimize capacitor lead lengths.
Bypass the reference inputs with $0.1 \mu \mathrm{~F}$ capacitors, as shown in Figures 7a, 7b, and 7c.

Analog Inputs
Figure 8 shows the equivalent circuit of the MAX113/ MAX117 input. When a conversion starts and $\overline{W R}$ is low, Vin is connected to sixteen 0.6 pF capacitors. During this acquisition phase, the input capacitors charge to the input voltage through the resistance of the internal analog switches. In addition, about 22 pF of stray capacitance must be charged. The input can be modeled as an equivalent RC network (Figure 9). As source impedance increases, the capacitors take longer to charge.
The typical $32 p F$ input capacitance allows source resistance as high as $1.5 \mathrm{k} \Omega$ without setup problems. For larger resistances, the acquisition time (tACQ) must be increased.
Internal protection diodes, which clamp the analog input to VDD and GND, allow the channel input pins to swing from GND - 0.3V to VDD + 0.3V without damage. However, for accurate conversions near full scale and zero scale the inputs must not exceed VDD by more than 50 mV or be lower than GND by 50 mV .

Figure 8. Equivalent Input Circuit

Figure 9. RC Network Equivalent Input Model

Figure 10. Transfer Function

# +3V, 400ksps, 4/8-Channel, 8-Bit ADCs with 1 1 A Power-Down 

If the analog input exceeds 50 mV beyond the supplies, limit the input current to no more than two milliamperes, as excessive current will degrade the conversion accuracy of the on channel.

Track/Hold
The track/hold enters hold mode when a conversion starts ( $\overline{R D}$ low or $\overline{W R}$ low). INT goes low at the end of the conversion, at which point the track/hold enters track mode. The next conversion can start after the minimum acquisition time, tACQ.

Transfer Function
Figure 10 shows the MAX113/MAX117's nominal transfer function. Code transitions occur halfway between successive-integer LSB values. Output coding is binary with 1LSB $=\left(\mathrm{V}_{\text {REF }}+-\mathrm{VREF}_{-}\right) / 256$.

## Conversion Rate

The maximum sampling rate (fmAX) for the MAX113/ MAX117 is achieved in write-read mode (tRD < tINTL) and is calculated as follows:

$$
\begin{aligned}
& \mathrm{f}_{\mathrm{MAX}}=\frac{1}{\mathrm{t}_{\mathrm{WR}}+\mathrm{t}_{\mathrm{RD}}+\mathrm{t}_{\mathrm{RI}}+\mathrm{t}_{\mathrm{ACQ}}} \\
& \mathrm{f}_{\mathrm{MAX}}=\frac{1}{600 \mathrm{~ns}+800 \mathrm{~ns}+300 \mathrm{~ns}+450 \mathrm{~ns}} \\
& \mathrm{f}_{\mathrm{MAX}}=465 \mathrm{kHz}
\end{aligned}
$$

where $\mathrm{tWR}=$ the write pulse width, tRD $=$ the delay between write and read pulses, tRI $=\overline{\mathrm{RD}}$ to $\overline{\mathrm{INT}}$ delay, and $t_{A C Q}=$ minimum acquisition time .

## Signal-to-Noise Ratio and Effective Number of Bits

Signal-to-noise plus distortion (SINAD) is the ratio of the fundamental input frequency's RMS amplitude to all other ADC output signals. The output spectrum is limited to frequencies above DC and below one-half the ADC sample rate.

The theoretical minimum analog-to-digital noise is caused by quantization error, and results directly from the ADC's resolution: $S N R=(6.02 N+1.76) d B$, where N is the number of bits of resolution. Therefore, a perfect 8-bit ADC can do no better than 50dB.

The FFT Plot (see Typical Operating Characteristics) shows the result of sampling a pure 30.27 kHz sinusoid at a 400 kHz rate. This FFT plot of the output shows the output level in various spectral bands.
The effective resolution (or "effective number of bits") the ADC provides can be measured by transposing the equation that converts resolution to SNR: $\mathrm{N}=(\mathrm{SINAD}$ 1.76) / 6.02 (see Typical Operating Characteristics).

Total Harmonic Distortion Total harmonic distortion (THD) is the ratio of the RMS sum of all harmonics of the input signal (in the frequency band above DC and below one-half the sample rate) to the fundamental itself. This is expressed as:

$$
T H D=20 \log \left[\frac{\sqrt{V_{2}^{2}+V_{3}^{2}+V_{4}^{2}+\ldots V_{N}^{2}}}{V_{1}}\right]
$$

where $\mathrm{V}_{1}$ is the fundamental RMS amplitude, and $\mathrm{V}_{2}$ through $\mathrm{V}_{\mathrm{N}}$ are the amplitudes of the 2nd through Nth harmonics.

Spurious-Free Dynamic Range Spurious-free dynamic range (SFDR) is the ratio of the fundamental RMS amplitude to the amplitude of the next largest spectral component (in the frequency band above DC and below one-half the sample rate). Usually the next largest spectral component occurs at some harmonic of the input frequency. However, if the ADC is exceptionally linear, it may occur only at a random peak in the ADC's noise floor. See the Signal-to-Noise Ratio graph in Typical Operating Characteristics.
